The proteome expanding effects of alternative pre-mRNA splicing have had a profound impact on euakaryotic evolution. The events that create this diversity can be placed into four major classes: exon skipping, intron retention, alternative 5’ splice sites, and alternative 3’ splice sites. Although the regulatory mechanisms and evolutionary pressures among alternative splicing classes clearly differ, how these differences affect the evolution of splicing regulation remains poorly characterized. We used RNA-seq to investigate splicing differences in D. simulans, D. sechellia, and three strains of D. melanogaster. Regulation of exon skipping and tandem alternative 3’ splice sites (NAGNAGs) were more divergent than other splicing classes. Splicing regulation was most divergent in frame-preserving events and events in noncoding regions. We further determined the contributions of cis- and trans-acting changes in splicing regulatory networks by comparing allele-specific splicing in F1 interspecific hybrids, because differences in allele-specific splicing reflect changes in cis-regulatory element activity. We find that species-specific differences in intron retention and alternative splice site usage are primarily attributable to changes in cis-regulatory elements (median ~80% cis), whereas species-specific exon skipping differences are driven by both cis- and trans-regulatory divergence (median ~50% cis). These results help define the mechanisms and constraints that influence splicing regulatory evolution and show that networks regulating the four major classes of alternative splicing diverge through different genetic mechanisms. We propose a model in which differences in regulatory network architecture among classes of alternative splicing affect the evolution of splicing regulation.

[Supplemental material is available for this article.]

Alternative pre-mRNA splicing is a central process in euakaryotic gene expression. The combination of exon sequences from single genomic loci into multiple isoforms greatly expands the proteome, magnifying the diversity of functional gene products from a comparably smaller number of genes (Nilsen and Graveley 2010). Alternative splicing is regulated through complex networks comprised of cis-regulatory sequence elements and trans-acting factors (Wang and Burge 2008). Three sequence elements interact directly with components of the spliceosome and are required for splicing of each intron: the 5’ splice site, the branchpoint, and the 3’ splice site. The sequences of these elements can modulate their “strength”—the probability that they will be recognized by the spliceosome. Additional elements in both introns and exons can act as splicing enhancers or silencers. Two families of trans-acting regulatory proteins, hnRNPs and SR proteins, which generally repress and enhance interactions with the core spliceosome, respectively, recognize splicing enhancers and silencers.

Four major classes of alternative splicing events can be broadly defined: exon skipping (SE), intron retention (RI), alternative 5’ splice sites (ASS), and alternative 3’ splice sites (A3SS) (Fig. 1B). Comparative genomic analyses suggest significant differences in the regulation and evolution of splicing classes. Compared with constitutive exons, skipped exons tend to have weaker splice sites and higher sequence conservation (Clark and Thanaraj 2002; Koren et al. 2007; Merkin et al. 2012), which may reflect selective pressure to maintain the binding sites of splicing regulatory proteins. In contrast, intron retention appears to be largely dependent on intron length and cis-regulatory sequence elements recognized directly by the spliceosome (Sakabe and de Souza 2007). Alternative 5’ and 3’ splice sites appear to originate via mutations in ancestral constitutive exons, creating new splice sites that compete with the original sites (Koren et al. 2007). Perhaps the simplest examples of this involve tandem alternative 3’ sites, a specific subclass of A3SS events separated by a single NAG (commonly referred to as “NAGNAGs”). Gains and losses of NAGNAG sites have accelerated protein evolution (Bradley et al. 2012). The relative strength of alternative 5’ and 3’ splice sites is correlated with their usage, however, only when the competing sites are in close proximity (Chasin 2007). Surprisingly, splicing regulatory sequences can modulate alternative 5’ splice site usage through direct interaction with the spliceosome, bypassing the need for trans-acting protein factors (Yu et al. 2008).

Species-specific differences in exon skipping are common and imply that splicing regulatory divergence could contribute to phenotypic variation. Early work revealed that ~7%–10% of exon skipping events were differentially regulated in human and chimpanzee liver and brain samples (Calarco et al. 2007; Blekhman et al. 2010; Lin et al. 2010). More recently, extensive comparisons in multiple tissues from numerous vertebrate species showed that exon skipping is diverging more rapidly than transcript abundance.
retained intron correlates with RNA-seq estimates of divergent splicing. A similar survey from Drosophila F1 hybrid head tissue reported 65 genes showing cis-acting differences in alternative isoform expression (Graze et al. 2012).

Results from other studies suggest that changes in the activity or abundance of trans-acting factors may contribute to divergent splicing. The expression levels of splicing regulatory proteins vary between species, suggesting trans-acting network changes (Grosso et al. 2008). In addition, the SR and hnRNP families of splicing regulatory proteins have evolved through numerous duplication and divergence events, highlighting the potential for trans-regulatory changes in splicing regulatory networks (Busch and Hertel 2011). For example, the testes-specific splicing regulator LS2 evolved from duplication of the constitutive splicing factor U2AF50 in Drosophila. The targets of LS2 have diverged substantially from those of U2AF50, leading to its current function as a splicing repressor (Taliaferro et al. 2011). Thus, changes in trans-acting factor abundance, activity, or specificity could be an important source of splicing regulatory evolution. As a result, the relative contributions of cis- and trans-regulatory changes toward divergence of alternative splicing remain uncertain. Furthermore, differences in the regulatory networks controlling the four classes of alternative splicing could affect the evolution of splicing regulation.

Here we used RNA-seq to compare alternative splicing in multiple D. melanogaster strains and one strain each of its closest phylogenetic relatives, D. sechellia and D. simulans. This choice of species allows us to sample a divergence time that is intermediate between that of previous studies investigating strains of C. elegans (Li et al. 2010) and vertebrate species (Barbosa-Morais et al. 2012; Merkin et al. 2012). Divergence of alternative splicing increases over evolutionary time, from ~5% among D. melanogaster strains to ~10% between species. Regulation of alternative splicing events in protein-coding regions was roughly half as likely to be divergent compared with noncoding regions. Of the coding region events that do exhibit divergent splicing, frame-shifting splicing events were half as likely to be divergent. Although skipped exons are known to have highly conserved sequences, we found that they are the most likely class of events to have interspecific differences in regulation. Alternative 3’ splice sites were also highly divergent, due mostly to divergence of NAGNAG tandem acceptor sites. Species-specific differences in splice site strength influenced divergent regulation at A3SS, much more than other classes of alternative splicing.

To estimate the relative effects of cis- and trans-acting regulatory changes in alternative splicing, we further compared allele-specific alternative splicing in hybrids of these species. In F1 hybrids, pre-mRNA from both parental alleles are subject to the same regulatory environments, thus observed differences in allele-specific splicing reflect cis-regulatory divergence. We used this approach previously to dissect cis- and trans-regulatory changes in miRNA abundance (McManus et al. 2010a). By applying this to alternative splicing, we find that divergent regulation of intron retention and alternative splice sites has occurred almost exclusively through changes in cis-acting sequences, while divergence of exon skipping results from both cis and trans-acting regulatory changes. Intriguingly, exon skipping is the most dynamic class of alternative splicing throughout D. melanogaster development, suggesting that divergent exon skipping was more frequent in transcripts encoding RNA-binding proteins (Barbosa-Morais et al. 2012) and in protein domains targeted for phosphorylation (Merkin et al. 2012). Together these studies demonstrate considerable divergence of exon skipping. In comparison, the extent of divergence in other alternative splicing classes remains poorly characterized. The genetic mechanisms of splicing regulatory evolution are also unclear.

Comparative studies of C. elegans strains point toward cis-acting variants as the main contributors to divergent exon skipping. Although both cis- and trans-acting differences can affect strain-specific exon skipping (Barberan-Soler and Zahler 2008), 77% of strain-specific alternative splicing quantitative trait loci appear to act locally, which suggests changes in cis-regulatory elements (Li et al. 2010). Similarly, Lin et al. (2010) found that divergent exon skipping events in humans and chimpanzees were associated with increased sequence divergence, suggesting that changes in cis-regulatory elements could be responsible for divergent splicing. However, divergent exon skipping in humans and chimpanzees was not associated with changes in splice site strength or density of exonic splicing regulatory elements (Irimia et al. 2009). More recently, the splicing patterns of 13 human exons were examined in a transgenic mouse, revealing that cis-regulatory changes contributed significantly to interspecies differences in exon skipping (Barbosa-Morais et al. 2012).
this class of alternative splicing may have more trans-regulatory factors than intron retention and alternative splice sites. Taken together, our results support a model in which differences in regulatory network architecture among alternative splicing classes affect the evolution of splicing regulation.

Results
Comparing alternative splicing among closely related Drosophila species

We used paired-end RNA-seq to compare alternative splicing in 2- to 10-d-old adult female flies from three closely related Drosophila species: D. melanogaster, D. sechellia, and D. simulans. We also measured alternative splicing in three strains of D. melanogaster—the original genome project strain (Celniker et al. 2002), the cosmopolitan strain zhr (Sawamura et al. 1993), and the African-type strain z30 (Wu 1995)—to compare inter- and intra-specific splicing divergence (Fig. 1A). The publicly available genome assemblies of these species are of vastly different quality. The genomes of D. melanogaster, D. sechellia, and D. simulans were originally sequenced to ~12-, five-, and threefold coverage, respectively (Drosophila 12 Genomes Consortium 2007). In addition, the strains used in our study likely differ from the reference genome to various extents. Differences in genome quality could complicate comparisons of alternative splicing. To avoid these complications, we resequenced the genomes of the strains (Coon et al. 2012) and species used in this study to an average of 26-fold coverage. This further increased the size of the D. sechellia and D. simulans assemblies by 1.6 and 12.6 Mbp, respectively, and corrected, on average, 806,805 SNPs and indels per strain (Supplemental Table S1), improving our ability to map RNA-seq reads from each sample. Paired-end cDNA sequencing resulted in an average of 18.9 million read pairs from each sample, with ~3.2 million reads per sample aligning uniquely to exon-junction databases (Supplemental Table S2).

We used exon-junction reads to determine splicing differences for the four major types of alternative splicing: skipped exons (SE), retained introns (RI), alternative 5' splice sites (ASSS), and alternative 3' splice sites (A3SS) (Fig. 1B). These events were extracted from the D. melanogaster transcriptome annotation generated from the modENCODE developmental time course analysis (Graveley et al. 2011). A minimum threshold of 20 exon-junction reads per splicing event in all samples allowed comparisons of 193 SE, 772 RI, 71 ASSS, and 559 A3SS events. The “percent spliced in” (PSI) metric was calculated for splicing events from each sample, and Fisher's exact tests were used to identify significant pairwise differences between PSI values (ΔPSI ≥ 10%; FDR ≤ 5%) (Wang et al. 2008). The validity of the RNA-seq splicing analysis pipeline was confirmed using semiquantitative RT-PCR (Fig. 1C) for six SE and four RI events. In both cases, the RNA-seq and RT-PCR PSI values agreed (Supplemental Fig. S1; R² = 0.84, N = 50).

Because we generated sequence data from species with multiple divergence times, our data set allows us to compare changes in splicing regulation with evolutionary divergence. D. melanogaster is estimated to have last shared a common ancestor with D. simulans and D. sechellia ~2.5 million yr ago (Cutter 2008), D. simulans and D. sechellia are thought to have diverged 0.25 million yr ago (Garrigan et al. 2012), and the North American and African D. melanogaster strains we used shared common ancestors ~10,000 yr ago (David and Capy 1988; Lachaise et al. 1988). Splicing regulatory divergence was highly correlated with sequence divergence (Pearson’s R² = 0.94; Supplemental Fig. S2). This correlation between the frequency of splicing divergence and divergence time was significant over all events (P = 0.029). Separating the splicing events by type (Supplemental Table S3) indicated that this correlation was strongest for SE (R² = 0.90; P < 0.05) and A3SS events (R² = 0.93, P = 0.035), was comparatively weaker for RI (R² = 0.77; P < 0.13), and not significant for ASSS events (R² = 0.5; P = 0.29). These data support the conclusion that alternative splicing regulatory divergence increases with divergence time.

Since many alternative splicing events are tissue specific, interspecies differences in relative tissue abundance could result in inaccurate inferences of divergent splicing regulation. To investigate this potential caveat, we looked for enrichment of genes with tissue-specific functions using gene ontology analysis (GO). Of the splicing events analyzed, genes exhibiting divergent splicing were not enriched for any GO categories. To further examine possible links between tissue abundance and splicing divergence, we asked whether genes with divergent splicing were enriched in species differences in mRNA abundance, calculated as described previously (McManus et al. 2010a). In all comparisons, divergently spliced genes were no more likely to be divergently expressed than genes with conserved splicing (Supplemental Table S4). Thus, differences in tissue-specific expression do not appear to impact our analyses of alternative splicing divergence.

Differences in splicing regulatory divergence among classes of alternative splicing

There are several differences in the regulatory divergence of the four classes of alternative splicing. SE events differed the most both among and between species, with 5.4% to 12.6% of these events showing divergent alternative splicing. SE events were 1.8–2.2-fold more likely to be divergent than other alternative splicing types in most intra- and interspecific comparisons (FET; P < 0.04) (Fig. 2A). NAGNAGs were also particularly divergent (Fig. 2B). Up to 23% of NAGNAG sites had divergent regulation. In fact, NAGNAGs are two to three times more likely to be divergent than non-NAGNAG A3SS events (FET; P = 0.021 D. mel vs. D. sec; P = 0.002 D. mel vs. D. simulans). Thus, exon skipping and tandem alternative 3' splice sites are the most divergent subgroups of alternative splicing.

Alternative splicing can alter mRNA sequence both in protein-coding and noncoding regions. Consequently, divergent splicing regulation can affect either the sequence of the resulting protein or regulatory regions. We compared the relative frequency of divergent splicing in coding and noncoding regions. Considering all classes of alternative splicing, events located in noncoding regions were more likely to be divergent than coding region events (Table 1). This enrichment of regulatory divergence in noncoding regions was significant for D. melanogaster/D. sechellia comparisons (2.05-fold enrichment, FET P = 7.8 × 10⁻⁵), but not for other interspecific comparisons. However, increased divergence of events in noncoding regions may be partially masked by the highly divergent NAGNAGs as ~90% of NAGNAGs are located in coding regions. After excluding NAGNAG events, enriched divergence in noncoding regions was even more apparent (1.5- to 2.4-fold) (Table 1).

In protein-coding regions, alternative splicing can either maintain the phase of the open reading frame, or more drastically affect the ORF by shifting the reading frame. Due to their less extreme effects on protein-coding sequences, we reasoned that regulation of frame-preserving splicing events would be more divergent between species. Indeed, frame-preserving events were
roughly twice as likely to be divergent when compared with frame-shifting events (Table 1) \((FET; P < 0.003)\). This enriched divergence of frame-preserving events is seen even when NAGNAG events are excluded \((P = 0.023)\) (Table 1). These results show that regulation of alternative splicing diverges more rapidly in noncoding regions than in coding regions and (within coding regions) in frame-preserving events than in frame-shifting events.

Sequences flanking splice sites play an important role in alternative splicing by affecting splice site strength. For example, the difference in strength at proximal and distal NAGNAG splice sites is correlated with their relative usage \((Bradley et al. 2012)\). Likewise, the combined strengths of the 5’ and 3’ splice sites of skipped exons correlates with their inclusion levels \((Baek and Green 2005; Shepard et al. 2011)\). To investigate the relationship between splice site strength and alternative splicing in our data set, we retrained the MaxEntScan scoring system \((Yeo and Burge 2004)\) using \(D. melanogaster\) splice site sequences and calculated maximum entropy scores for each species and strain. As expected, we found correlations in splice site strength and relative usage of alternative 5’ and 3’ splice sites \((R^2 = 0.373; R^2 = 0.404; P < 10^{-16})\). Similarly, the combined strength of donor and acceptor sites was correlated with exon skipping and intron retention \((R^2 = 0.105; R^2 = 0.291; P < 10^{-16})\). These results show that splice site strength is an important determinant of A5SS, A3SS, and RI alternative splicing levels in \(Drosophila\), with less influence over SE events.

The correlation between splice site strengths and PSI values suggests that mutations affecting site strength might contribute to splicing regulatory evolution. To directly investigate this possibility, we compared differences in splice site strength with differences in PSI for \(D. melanogaster, D. simulans,\) and \(D. sechellia\). Weak significant correlations were seen between species-specific differences in splice site strength and splicing inclusion for A3SS and RI events.

but not for SE and A5SS events (Table 2). Compared to other alternative splicing types, NAGNAG events showed the highest correlation of change in site strength with change in splicing regulation ($R^2 = 0.16–0.18$; $P < 10^{-5}$) (Table 2). Thus, mutations affecting splice site strength contribute to divergent regulation of tandem $3'$ splice sites, and have little to no effect on RI, A5SS, and SE regulation.

Cis- and trans-regulatory differences underlying divergent alternative splicing

After identifying interspecific differences in alternative splicing, we next addressed the relative contributions of cis- and trans-acting differences in splicing regulation using interspecies F1 hybrids. In F1 hybrid nuclei, pre-mRNAs from both parental alleles are exposed to the same trans-regulatory environment. This normalization of trans-acting factors means that allele-specific splicing differences in hybrids reflect differences in pre-mRNA cis-regulatory elements. Trans-acting contributions can then be inferred by comparison of interspecific differences with allele-specific differences in the hybrid (Wittkopp et al. 2004). We compared allele-specific alternative splicing levels in two F1 hybrids, resulting from crosses of $D. melanogaster$ with $D. sechellia$, and $D. simulans$, respectively, to determine the contributions of cis- and trans-acting regulatory differences to divergent alternative splicing. Paired-end sequencing of RNA isolated from adult females resulted in 49.8 million read-pairs from the $D. simulans \times D. melanogaster$ hybrids and 54.1 million read-pairs from the $D. sechellia \times D. melanogaster$ hybrids. Similar transcriptome coverage was obtained from mixed-control cDNA libraries prepared from a mixture of equal concentrations of total mRNA from each parent (Supplemental Table S2). Sequence reads were aligned to genomes and splice-junction databases from each parental species to identify allele-specific reads that mapped uniquely to a single species without mismatches (McManus et al. 2010a). Paired-end sequencing of $D. melanogaster/D. simulans$ F1 hybrids resulted in an effective read-length of 152 bp, thereby allowing identification of allele specificity for ~73% of genomic and 82% of splice-junction reads. Data from $D. melanogaster \times D. sechellia$ hybrids included published 2 × 37-bp read pairs (McManus et al. 2010a), resulting in a somewhat lower fraction of allele-specific read assignments (Supplemental Table S2).

Bioinformatic analyses can introduce errors in assigning reads to alleles (Degner et al. 2009), largely due to alignment bias in favor of alleles that more closely match a reference genome. Aligning reads to allele-specific genomes, as was done for this study, alleviates most of these errors (Stevenson et al. 2013). We used two approaches to assess the performance of our allele-specific splicing analysis pipeline. First, we used allele-specific RT-PCR (McManus et al. 2010b) to measure ΔPSI values from separate species and F1 hybrids for seven RI and eight SE events. Allele-specific ΔPSI values measured via RT-PCR were consistent with RNA-seq measurements ($R^2 = 0.70$; N = 60; Supplemental Fig. S3). As a second approach to assess our allele-specific analysis pipeline, we compared PSI estimates from separate species mRNA libraries with allele-specific PSI values from libraries made by mixing equal amounts of two species mRNA (“mix-control”). PSI values from separate species samples correlate quite well with allele-specific PSIs from the mix-control libraries (average $R^2 = 0.94$; Supplemental Table S5). However, ΔPSI values between species were less well-correlated (average $R^2 = 0.48$; Supplemental Table S5). To avoid potential errors, we focused on “well-behaved” splicing events—events for which separate and allele-specific ΔPSI values varied by <10%. This subset includes ~70% of the alternative splicing events used in interspecific comparisons. Together, these results indicate that our bioinformatic analysis of allele-specific alternative splicing performs well.

We compared $D. melanogaster$ to $D. simulans$ and $D. sechellia$ to determine the number of alternative splicing events with cis- and trans-regulatory differences. Example cis- and trans-acting differences in alternative splicing are shown in Figure 3. Of the 983 well-behaved splicing events in the $D. melanogaster/D. simulans$ comparison, 64 had divergent regulation, 36 exhibited cis-, and 10 had trans-regulatory divergence (FDR = 0.05). The higher frequency of cis-regulatory (compared to trans-regulatory) differences was also seen in the $D. melanogaster/D. sechellia$ comparison. Of 681 well-behaved splicing events, 32 were divergently regulated, and 19 and three events exhibited cis- and trans-regulatory divergence, respectively (FDR = 0.05). Thus, more alternative splicing events are affected by divergence in cis-regulatory elements than in trans-acting factors.

Differences in regulatory network structure among the four major types of alternative splicing could impact the evolution of splicing regulation. To examine this, we determined the relative frequency of cis- and trans-acting regulatory changes in each splicing class. While cis-regulatory changes were most prevalent among RI, A5SS, and A5SS events, many SE events exhibited trans-regulatory changes (Fig. 4A; Table 3). However, the existence of trans-regulatory differences does not, in and of itself, reflect the relative contribution of trans-regulatory divergence. To more directly evaluate the contributions of cis- and trans-regulatory changes on divergent splicing, we compared the fraction of divergent splicing attributable to cis-regulatory differences (% cis) (Wittkopp et al. 2008) among splicing classes. As shown in Figure 4B, SE events had significantly lower % cis than other splicing classes, indicating that cis-regulatory changes contribute less to exon skipping divergence than to other classes of alternative splicing.

The importance of splice site strength for A5SS NAGNAG events could make them more susceptible to cis-regulatory divergence. We found that NAGNAG events were 3.7-fold and 7.4-fold more likely to diverge through cis-regulatory changes than non-NAGNAG events when comparing splicing in $D. melanogaster$ with $D. simulans$ and $D. sechellia$, respectively ($P < 0.026$, FET). For the eight cis-divergent NAGNAG events, five have mutations in the NAGNAG site that alter one of the two AGs in one or more species. Another site has a CAGCAG to AAGCAG mutation. CAG is a better match to $3'$ end consensus sequences than AAG (Mount et al. 1992), suggesting that this mutation shifts the balance in splice site strength. The
remaining two NAGNAG events with cis-regulatory divergence preserve the NAGNAG sequence, but have multiple mutations in the upstream intron sequence. Thus, NAGNAG sites are indeed hotspots for cis-regulatory changes, and most of the mutations responsible alter the NAGNAG sequence itself.

Discussion

Here we used RNA-seq to analyze the rate and mechanisms of alternative splicing regulatory evolution in Drosophila. While prior studies used this approach to examine the evolution of exon skipping (Barbosa-Morais et al. 2012; Merkin et al. 2012), the evolution of other types of alternative splicing remains largely unexplored. The four major classes of alternative splicing are regulated through different molecular mechanisms. Our results provide a unique comparison of regulatory divergence among splicing classes and suggest that differences in their underlying mechanisms of regulation strongly impact the course of their evolution.

We compared the regulation of SE, RI, A5SS, and A3SS among strains of D. melanogaster and its sister species D. simulans and D. sechellia. Our analysis shows that regulation of SE and NAGNAG events has diverged roughly twice as rapidly as other classes of alternative splicing. One interpretation of this result is that SE and NAGNAG regulatory networks are more pliable than other classes of alternative splicing. Increased pliability could reflect reduced selective pressure to maintain inclusion levels and/or increased

Figure 3. Cis- and trans-acting differences in alternative splicing. IGV Genome Browser images show RNA-seq read coverage, depicted in a bar graph (above). Arcs depict splice-junction read coverage (per million mapped junction reads). The width of each arc represents the relative number of junction reads. For exon skipping, exclusion junctions are shown in blue and inclusion junctions are shown in red. The percent spliced in (PSI) for each sample is shown above the alternative event. Gel images show the results of RT-PCR experiments using species-specific primers. (A) An intron in CG12006 is retained much more frequently in D. melanogaster than in D. sechellia. In F1 hybrids, allele-specific splicing differences show that the divergence is predominantly cis-acting. (B) An exon in nuf is skipped more frequently in D. melanogaster than in D. simulans. Allele-specific RNA-seq from F1 hybrids shows equal inclusion levels, suggesting that divergence in nuf splicing is predominantly trans-acting.

Figure 4. Exon skipping divergence is influenced more by differences in trans-acting factors than other classes of alternative splicing. (A) Percentage of alternative splicing events affected by cis- and trans-acting regulatory divergence for two F1 hybrid crosses. Skipped exons (SE) have many more events affected by trans-regulatory divergence. (B) Relative contribution of cis-regulatory divergence in divergent alternative splicing. The fraction of species-specific splicing differences attributable to cis-acting changes (% cis) is plotted for four classes of alternative splicing. Exon skipping has a much lower contribution from cis-acting changes, reflecting a higher contribution of trans-regulatory divergence. P-values indicate the results of Wilcoxon rank sum tests comparing the mean % cis of different alternative splicing types.

complexity of their regulatory networks. In the case of NAGNAGs, the former explanation seems most reasonable, as their usage alters only a single amino acid. Indeed, a recent study found that single codon insertions and deletions were greatly enriched at the 5′ ends of exons, consistent with frequent mutational gain and loss of NAGNAG sites (Bradley et al. 2012).

Divergent exon skipping is likely to have more significant effects on protein-coding sequences. As such, the rapid divergence of SE requires another explanation. Landry and colleagues have shown that mutational variance, or probability that a mutation affects the expression of a gene, is correlated with the number of cis- and trans-regulatory components that control a gene's expression (Landry et al. 2007). Genes with more complex regulatory networks are more susceptible to changes in their regulation. One possibility is that SE regulatory networks are more complex than those that control other types of alternative splicing. If this is true, we would expect SE to be more dynamically regulated than other splicing classes. To investigate this, we calculated the switch scores (Maximum PSI–Minimum PSI) of alternative splicing events across the lifecycle of D. melanogaster (Graveley et al. 2011) and compared switch scores between splicing classes (Fig. 5A). SE are the most developmentally dynamic of all splicing events, lending credence to the complexity model. Similarly, exon skipping events are more sensitive to RNAi-mediated knockdown of splicing factors in S2 cells (A Brooks, M Duff, G May, L Yang, J Landolin, K Wan, J Sandler, S Celniker, B Graveley, S Brenner, in prep.), suggesting that their trans-mutational target size is larger than that of other splicing classes. Thus the comparatively rapid divergence of exon skipping may reflect a higher complexity of SE regulatory networks.

The relative contributions of cis- and trans-regulatory differences to splicing divergence are still debated. While large-scale studies have reported different conclusions regarding the role of cis-regulatory changes in SE regulation (Irimia et al. 2009; Li et al. 2010; Lin et al. 2010), divergent skipping of 13 mouse and human exons was recently attributed mostly to cis-regulatory differences (Barbosa-Morais et al. 2012). Unlike the human and mouse comparison, we found that trans-regulatory divergence has contributed substantially to differences in exon skipping among Drosophila. Several studies have shown that cis-regulatory differences in mRNA abundance preferentially accumulate over evolutionary time (Wittkopp et al. 2008; Emerson et al. 2010; Coolon et al. 2014). Thus, one explanation for the larger importance of cis-regulatory divergence observed by Barbosa-Morais and colleagues could be that their study used a much more divergent set of species (mouse and human).

Prior to this study, comparatively little was known regarding regulatory evolution of other types of splicing events. We determined the contributions of cis- and trans-regulatory changes in all major classes of alternative splicing events by analyzing allele-specific splicing patterns in F1 hybrids. Surprisingly, we found that the genetic mechanisms responsible for splicing evolution varied between classes. Although species differences in RI, A3SS, and ASSS can be attributed almost entirely to cis-regulatory sequence differences, cis- and trans-regulatory changes have contributed more equally to divergent SE.

The regulatory evolution of mRNA abundance and alternative splicing appear to be on different trajectories, in both the rate and path of their divergence. Species differences in mRNA abundance are much more common than divergent splicing regulation, with at least a third of the transcriptome exhibiting divergent regulation across all major classes of alternative splicing events (Graveley et al. 2011). The median switch score (white dots) is highest for D. melanogaster, followed by D. simulans, D. sechellia, and D. melanogaster, respectively.

Figure 5. Differences in regulatory network architecture among classes of alternative splicing impact their regulatory divergence. (A) Skipped exons are more dynamically regulated throughout development. Violin plots show the distribution of switch scores (maximum percent inclusion minus minimum percent inclusion) for splicing events from each class of alternative splicing throughout development in D. melanogaster (Graveley et al. 2011). The median switch score (white dots) is highest for SE events. (B) Model of regulatory network differences among splicing classes. Skipped exons have a larger trans-mutational target size compared to other splicing classes and SE regulation diverges more rapidly through changes in trans-acting factors.
both within and between closely related species (Emerson et al. 2010; McManus et al. 2010a; Coolon et al. 2014). In contrast, changes in cis-regulatory sequences play a more prominent role in splicing regulatory evolution, and only SE events exhibited substantial trans-regulatory divergence. Intriguingly, higher complexity of SE regulatory networks would also be expected to increase their susceptibility to trans-regulatory divergence.

We propose a model in which the networks that regulate SE are more complex than those of other splicing classes. This increased complexity leads to more rapid divergence of SE and increased trans-regulatory changes by providing a larger mutational target area (Fig. 5B). Consistent with this model, we found that regulation of SE diverges more rapidly and is more influenced by trans-regulatory divergence than that of other splicing classes. In addition, exon skipping is much less sensitive to splice site strength, and changes in site strength contribute little to divergent splicing regulation. In summary, RI, A5SS, and A3SS are diverging almost entirely through cis-regulatory changes, while trans-regulatory divergence has a greater impact on SE. The differences in regulatory network architecture among classes of alternative splicing affect the evolution of splicing regulation. Because deep coverage is necessary for accurate splicing analysis, our results represent the evolutionary trajectory of events found on genes highly expressed in many tissue types. Future work utilizing richer sequence depth from specific tissues will be necessary to determine the extent to which our results are also applicable to tissue-specific alternative splicing.

**Methods**

**Flies and crosses**

Much of the data used in this study was previously reported. All data used in this study were obtained from adult female flies 2- to 10-d post eclosion grown on standard Drosophila media. Specific conditions for the *D. melanogaster* strain zhr carrying the hybrid rescuing Zhr1 chromosome [full genotype, XYS.YL.Df(1)Zhr]; (Sawamura et al. 1993; Ferree and Barbash 2009) and the Zimbabwean strain z30 (Begun and Aquadro 1993; Wu et al. 1995) were previously reported (Coolon et al. 2012). Conditions for the *D. melanogaster* genome reference strain 14021-0231.36 were also previously reported (Graveley et al. 2011). Conditions for *D. melanogaster* 14021-0231.36 × *D. sechellia* (14021-0428.25) hybrids were previously described (McManus et al. 2010a). The *D. simulans* tsimbaza strain (Holocher et al. 2000) and *D. melanogaster* zhr × *D. simulans* tsimbaza hybrids were grown as described by Coolon and colleagues (Coolon et al. 2012, 2014).

**Library preparation and sequencing**

Total RNA from each species was prepared by grinding 20 adult female flies in TRIzol (Invitrogen) and treated with DNase I (Ambion DNA-free) to remove DNA contaminants. RNA-seq libraries were prepared as previously described (McManus et al. 2010a). Ten micrograms of total RNA was used to prepare libraries for each pure species and hybrid sample, while 5 μg of each species RNA was mixed together for mixed samples. Poly(A)+ RNA was purified by two incubations with oligo-dT magnetic beads (Invitrogen Dynal), and fragmented using an RNA fragmentation reagent (Ambion). Reverse transcription was performed using random primers and SuperScript II (Invitrogen). Approximately 350 bp fragments of cDNA were purified by electrophoresis on a 2% agarose gel and extracted. Size-selected cDNA fragments were used as input material for library preparation using the Paired-end Genomic DNA library kit (Illumina). Genomic DNA was prepared using the DNeasy Blood and Tissue kit (Qiagen). A total of 10 μg of DNA was used as input material for the Paired-end Genomic DNA library kit (Illumina). Genomic DNA was fragmented using Illumina supplied nebulizers and size-selected as described above. Libraries were subjected to 76 cycles of paired end sequencing on an Illumina GA IIx. Basecalling was performed using Illumina CASSAVA. For total readcounts and depth of coverage, see Supplemental Material. Additional data from prior work was also included in this study and is available under SRA accession numbers SRA052065 (*D. melanogaster* zhr and z30 gDNA), SRA009364 (*D. melanogaster* reference strain 5-d adult female; modENCODE), and GEO accession number GSE20421 (*D. sechellia*, and hybrid mRNA).

**Genome resequencing and assembly**

Genomic sequence reads from *D. sechellia*, *D. simulans*, and *D. melanogaster* were aligned to the drosSec1, drosSim1, and dm3 assembly releases, respectively, using BWA (version 0.5.6) (Li and Durbin 2010). Reads were aligned separately using default parameters and indels were called using SAMtools (version 0.1.7a; commands view, sort, and pileup) (Li et al. 2009). SNPs and indels were filtered using the SAMtools package command “samtools.pl varfilter” to retain variants with phred quality scores greater than 20 (estimated 1% error). A custom Perl script, snp_adder.pl (Supplemental Material), was used to produce strain-specific genomes. This script modifies reference genome sequences to incorporate the filtered variants. Insertion/deletion positions were recorded and used to produce custom chain files to use with the UCSC liftOver script.

For *D. sechellia* and *D. simulans*, gDNA sequence reads were remapped to the strain-specific genomes. Nonmappable read-pairs were assembled into contigs using Velvet (version 1.0.15; parameters: velveth k=35; velvetg –exp_cov auto, -min_contig_lgth 300) (Zerbino and Birney 2008). These contigs were aligned to the strain-specific genomes using BLAT. Contigs whose 5’ and 3’ ends both align to the strain-specific genome were retained and extended 100 bp in each direction. These “extended” contigs span gaps in each organism’s genomic sequence. Extended contigs were combined with the strain-genome-specific genomes to create an intermediate target sequence for gDNA read alignment. Genomic DNA was remapped to this intermediate target genome, and nonmappable read-pairs were assembled into contigs as above. The resulting contigs were combined with extended contigs and aligned to the dm3 reference genome using LASTZ (Harris 2007). Contigs that aligned uniquely to the *D. melanogaster* reference genome (dm3) were kept as the “extra-genome.” LiftOver chain files were produced from the LASTZ alignment output using the axtChain, chainNet, and netChainSubset utilities from the UCSC Genome Browser (Kent et al. 2003).

Custom Perl scripts were used to create exon junction databases for allele-specific alignment, using gene annotations generated by the modENCODE Consortium (Graveley et al. 2011). Junction windows were chosen to require that each exon is covered by at least 6 nt of a junction read. “Exact” junctions were created to allow alignment to exons shorter than the read length (76 nt). In this case, a junction window would contain a sequence from more than two exons, x1–x2 (short) – x3, while maintaining the length of the junction window. Junction window genome coordinates from *D. melanogaster* were translated to each of the resequenced genomes using the UCSC liftOver tool. A sequence for each junction window was extracted and joined into “exact”
junction databases. Junction databases were filtered to remove junctions lacking defined coordinates in one or more species or strains. In order to identify RNA-seq reads relevant to intron retention, genomic coordinates overlapping the splice site by at least 6 nt were identified. Reads aligning to these regions were taken as evidence of intron retention.

Allele-specific alignment
At some genomic coordinates, gDNA resequencing identified heterogeneous sites. If ignored, these sites could introduce error in allele-specific alignment steps. Thus, target genomes for allele-specific alignment were produced by adding heterozygous sites to each strain’s genome using snp_adder.pl (Supplemental Material). IUPAC nucleotide codes were used to represent heterozygous sites (e.g., “R” for A/G heterozygote). RNA-seq reads were aligned to genomic and junction coordinates using MOSAIK (version 1.0.1388; parameters: -hs 13 -mm 0 -j -mhp 100 –act 20) (Busby et al. 2011).

For single-species RNA-seq samples, reads were aligned to the corresponding genome and junction sequences. For mixed (e.g., D. melanogaster RNA + D. simulans RNA) and F1 hybrid samples, reads were aligned sequentially to each genome in order to identify allele-specific alignments. The alignment procedure was essentially performed as previously reported (McManus et al. 2010a). Reads were first aligned to genome sequences. Reads that failed to align to genomic loci were then aligned to exon junction sequences. Remaining RNA-seq reads were trimmed 13 nt and realigned for four total cycles (76, 63, 50, and 37 nt). Alignment coordinates were converted to bed format using MOSAIK, with a correction step to convert MOSAIK BED files (1-based) to proper BED format (0-based). Genomic alignment coordinates for each species and strain were then converted to the corresponding locations in the D. melanogaster reference genome using the UCSC liftOver tool and custom chain files. RNA-seq reads mapping to unique genomic coordinates (without mismatches) in a single species were considered allele specific and used in further analyses.

Splicing analysis
Gene annotations were sorted into four alternative splicing event categories (exon skipping, alternative 5’ splice sites, alternative 3’ splice sites, and intron retention). The intersectBed program (Quinlan and Hall 2010) was used to identify genomic reads that crossed splice sites from annotated intron retention events. Custom Perl scripts parsed the junction database alignments to count the RNA-seq reads corresponding to each event. These scripts create tables of junction and genomic hits for each splicing event (Supplemental Tables S6–S9). Splicing analysis was performed for all events with a minimum of 20 total RNA-seq reads (junctions for exon skipping and alternative splice sites, junction and genomic reads for intron retention). The 20-read threshold was chosen based on prior work (Pan et al. 2008; Wang et al. 2008). However, the results of our analysis are essentially the same using a lower 10-read threshold (Supplemental Fig. S4). Percent Spliced In (PSI) values were calculated using the following formulas.

Exon skipping

\[ PSI = \left( \frac{\sum H - \sum F}{\sum H + \sum F} \right) \times 100. \]

Two common exons, “C1” and “C2,” flank an alternative exon, “A.” When “A” is longer than the read length (76), two junctions support exon inclusion, C1–A and A–C2. When A is shorter than the read length, the C1–A–C2 junction can also be identified in RNA-seq data. Together, the C1–A, A–C2, and C1–A–C2 junctions are defined as inclusion junctions (IJ), while C1–C2 are exclusion junctions (EJ).

Alternative splice sites

\[ PSI = \left( \frac{\sum DA}{\sum D_A + \sum D_{A2}} \right) \times 100. \]

Alternative splice sites are defined as sites with either one 5’ donor site and two alternative 3’ acceptor sites (alternative 3’ss), or two alternative 5’ donor sites and one 3’ acceptor site (alternative 5’ss). In both situations, two alternative splice junctions are possible. Alternative 3’ss allow DA1 (donor-acceptor1) and DA2 (donor-acceptor 2), while alternative 5’ss allow D1A and D2A junctions.

Intron retention

\[ PRI = \left( \frac{\sum DI + \sum IA}{\sum DA + \sum DI + \sum DA} \right) \times 100. \]

A total of 776 retained introns annotated in the modENCODE survey of developmental gene expression (Graveley et al. 2011) were analyzed for regulatory divergence. Intron retention analysis was restricted to introns with single donor and acceptor splice sites. Junction sequences joining the donor and acceptor (DA) supported intron splicing, while sequence reads that aligned across the donor or acceptor sites into the intron (DI and IA) by at least 6 nt suggested intron retention. Percent retained intron (PRI) was calculated. While all of these events had retention frequencies >5% in at least one developmental time point from the modENCODE study, 46 (6%) did not appear to be retained in any of the adult females we surveyed.

Tests of statistical significance were performed using R. Fisher’s exact test was used to compare PSI values for each pairwise comparison of strains and species. Q-values were calculated using the qvalue module in R (Storey and Tibshirani 2003). Q-value cutoffs corresponding to an FDR of 0.05 were applied. In addition, only splicing events for which both samples had ≥20 informative junction reads and PSI differences ≥PSI >10% were considered further. Comparisons of allele-specific PSI values from F1 hybrid samples were also performed using Fisher’s exact test to identify cis-acting differences in splicing. The ratio of PSI values between parent alleles (e.g., D. melanogaster/D. simulans) were compared to allele-specific PSI ratios from hybrids using the method of Altman and Bland (2003). The standard error of the difference in parental and allele-specific PSI ratios was calculated and used to calculate Z-scores and P-values. Q-values were further calculated and an FDR cutoff of 0.05 was applied to tests of cis- and trans-acting splicing divergence. Less stringent FDR thresholds of 0.1 and 0.2 were tested and gave highly similar results. Interspecies differences in mRNA abundance were compared as described (McManus et al. 2010a), and divergent expression and splicing were cross-compared using Fisher’s exact test in R.

Validation
Species-specific RT-PCR (McManus et al. 2010b) was used to validate cis- and trans-acting differences in alternative splicing. Seven
events from RI and eight events from SE were chosen for validation. Primers were designed such that the 3′ ends of each primer crossed SNPs. Total RNA was reverse transcribed using random primers and SuperScript II reverse transcriptase according to the manufacturer’s specifications (Invitrogen). cDNA was amplified for 30 cycles using species-specific primers and Taq (Invitrogen). PCR products were separated on 2% agarose gels and visualized by ethidium bromide staining. Gel images were processed with ImageJ (Schneider et al. 2012) to quantify products. PSI values were calculated by normalizing brightness by PCR product length. RNA-seq and RT-PCR PSI values were compared for linear correlation using R.

Data access

High-throughput sequencing data have been submitted to the NCBI Sequence Read Archive (SRA; http://www.ncbi.nlm.nih.gov/sra) under accession number SRP023274. Genome sequences are accessible at the McManus (http://www.bio.cmu.edu/labs/mcmanus/), Wittkopp (http://www.umich.edu/~pwalb/), and Graveley (http://graveleylab.cam.ucdh.edu/Graveley/) laboratory websites. Contigs with novel sequences from D. simulans and D. sechellia have been submitted to GenBank (http://www.ncbi.nlm.nih.gov/genbank/) under accession numbers JAQJ00000000 and JAQRO0000000, respectively.

Acknowledgments

We are grateful to the University of Connecticut Health Center Genomics Core Facility for providing access to Illumina Sequencers. We also thank Gene Yeo for assistance in retraining MaxEntScan splice site scoring models using D. melanogaster sequences and Kraig Stevenson for bioinformatic assistance.
